Glossary	xiv
Acronyms	xv
1 Introduction	1
1.1 Cancer Research in the Post-Genomic Era	1
1.1.1 Cancer as a Global Health Concern	2
1.1.1.1 The Genetics and Molecular Biology of Cancers	3
1.1.2 The Human Genome Revolution	6
1.1.2.1 The First Human Genome Sequence	6
1.1.2.2 Impact of Genomics	7
1.1.3 Technologies to Enable Genetics Research	7
1.1.3.1 DNA Sequencing and Genotyping Technologies	7
1.1.3.2 Microarrays and Quantitative Technologies	8
1.1.3.3 Massively Parallel “Next Generation” Sequencing	9
1.1.3.3.1 Molecular Profiling with Genomics Technology	11
1.1.3.3.2 Sequencing Technologies	11
1.1.3.4 Bioinformatics as Interdisciplinary Genomic Analysis	12
1.1.4 Follow-up Large-Scale Genomics Projects	13
1.1.5 Cancer Genomes	14
1.1.5.1 The Cancer Genome Atlas Project	15
1.1.5.1.1 Findings from Cancer Genomes	15
1.1.5.1.2 Genomic Comparisons Across Cancer Tissues	17
1.1.5.1.3 Cancer Genomic Data Resources	18
1.1.6 Genomic Cancer Medicine	18
1.1.6.1 Cancer Genes and Driver Mutations	18
1.1.6.2 Personalised or Precision Cancer Medicine	19
1.1.6.2.1 Molecular Diagnostics and Pan-Cancer Medicine	20
1.1.6.3 Targeted Therapeutics and Pharmacogenomics	21
1.1.6.3.1 Targeting Oncogenic Driver Mutations	21
1.1.6.4 Systems and Network Biology	22
1.1.6.4.1 Network Medicine, and Polypharmacology	24
1.2 A Synthetic Lethal Approach to Cancer Medicine	25
1.2.1 Synthetic Lethal Genetic Interactions	26
1.2.2 Synthetic Lethal Concepts in Genetics	26
1.2.3 Studies of Synthetic Lethality	27

1.2.3.1	Synthetic Lethal Pathways and Networks	28
1.2.3.1.1	Evolution of Synthetic Lethality	29
1.2.4	Synthetic Lethal Concepts in Cancer	29
1.2.5	Clinical Impact of Synthetic Lethality in Cancer	31
1.2.6	High-throughput Screening for Synthetic Lethality	33
1.2.6.1	Synthetic Lethal Screens	34
1.2.7	Computational Prediction of Synthetic Lethality	37
1.2.7.1	Bioinformatics Approaches to Genetic Interactions . .	37
1.2.7.2	Comparative Genomics	38
1.2.7.3	Analysis and Modelling of Protein Data	41
1.2.7.4	Differential Gene Expression	43
1.2.7.5	Data Mining and Machine Learning	44
1.2.7.6	Bimodality	47
1.2.7.7	Rationale for Further Development	48
1.3	E-cadherin as a Synthetic Lethal Target	48
1.3.1	The <i>CDH1</i> gene and it's Biological Functions	48
1.3.1.1	Cytoskeleton	49
1.3.1.2	Extracellular and Tumour Micro-Environment	49
1.3.1.3	Cell-Cell Adhesion and Signalling	49
1.3.2	<i>CDH1</i> as a Tumour (and Invasion) Suppressor	50
1.3.2.1	Breast Cancers and Invasion	50
1.3.3	Hereditary Diffuse Gastric Cancer and Lobular Breast Cancer .	50
1.3.4	Somatic Mutations	52
1.3.4.1	Mutation Rate	52
1.3.4.2	Co-occurring Mutations	52
1.3.5	Models of <i>CDH1</i> loss in cell lines	53
1.4	Summary and Research Direction of Thesis	54
2	Methods and Resources	58
2.1	Bioinformatics Resources for Genomics Research	58
2.1.1	Public Data and Software Packages	58
2.1.1.1	Cancer Genome Atlas Data	59
2.1.1.2	Reactome and Annotation Data	60
2.2	Data Handling	61
2.2.1	Normalisation	61
2.2.2	Sample Triage	61
2.2.3	Metagenes and the Singular Value Decomposition	63
2.2.3.1	Candidate Triage and Integration with Screen Data . .	63
2.3	Techniques	64
2.3.1	Statistical Procedures and Tests	64
2.3.2	Gene Set Over-representation Analysis	65
2.3.3	Clustering	66
2.3.4	Heatmap	66
2.3.5	Modeling and Simulations	66
2.3.5.1	Receiver Operating Characteristic (Performance) . . .	67
2.3.6	Resampling Analysis	68

2.4	Pathway Structure Methods	69
2.4.1	Network and Graph Analysis	69
2.4.2	Sourcing Graph Structure Data	70
2.4.3	Constructing Pathway Subgraphs	70
2.4.4	Network Analysis Metrics	70
2.5	Implementation	71
2.5.1	Computational Resources and Linux Utilities	71
2.5.2	R Language and Packages	73
2.5.3	High Performance and Parallel Computing	75
3	Methods Developed During Thesis	77
3.1	A Synthetic Lethal Detection Methodology	77
3.2	Synthetic Lethal Simulation and Modelling	80
3.2.1	A Model of Synthetic Lethality in Expression Data	80
3.2.2	Simulation Procedure	84
3.3	Detecting Simulated Synthetic Lethal Partners	87
3.3.1	Binomial Simulation of Synthetic lethality	87
3.3.2	Multivariate Normal Simulation of Synthetic lethality	89
3.3.2.1	Multivariate Normal Simulation with Correlated Genes	92
3.3.2.2	Specificity with Query-Correlated Pathways	99
3.3.2.2.1	Importance of Directional Testing	99
3.4	Graph Structure Methods	101
3.4.1	Upstream and Downstream Gene Detection	101
3.4.1.1	Permutation Analysis for Statistical Significance	102
3.4.1.2	Hierarchy Based on Biological Context	103
3.4.2	Simulating Gene Expression from Graph Structures	104
3.5	Customised Functions and Packages Developed	108
3.5.1	Synthetic Lethal Interaction Prediction Tool	108
3.5.2	Data Visualisation	109
3.5.3	Extensions to the iGraph Package	111
3.5.3.1	Sampling Simulated Data from Graph Structures	111
3.5.3.2	Plotting Directed Graph Structures	111
3.5.3.3	Computing Information Centrality	112
3.5.3.4	Testing Pathway Structure with Permutation Testing	112
3.5.3.5	Metapackage to Install iGraph Functions	113
4	Synthetic Lethal Analysis of Gene Expression Data	114
4.1	Synthetic lethal genes in breast cancer	115
4.1.1	Synthetic lethal pathways in breast cancer	117
4.1.2	Expression profiles of synthetic lethal partners	118
4.1.2.1	Subgroup pathway analysis	121
4.2	Comparison of synthetic lethal gene candidates	124
4.2.1	Comparison with siRNA screen candidates	124
4.2.1.1	Comparison with correlation	125
4.2.1.2	Comparison with viability	126
4.2.1.3	Comparison with secondary siRNA screen candidates	130

4.2.1.4	Comparison of screen at pathway level	130
4.2.1.4.1	Resampling of genes for pathway enrichment . .	132
4.3	Metagene Analysis	138
4.3.1	Pathway expression	138
4.3.2	Somatic mutation	141
4.3.3	Mutation locus	142
4.3.4	Synthetic lethal metagenes	144
4.4	Replication in stomach cancer	145
4.4.1	Synthetic Lethal Genes and Pathways	146
4.4.2	Synthetic Lethal Expression Profiles	148
4.4.3	Comparison to Primary Screen	150
4.4.3.1	Resampling Analysis	151
4.4.4	Metagene Analysis	151
4.5	Global Synthetic Lethality	152
4.5.1	Hub Genes	153
4.5.2	Hub Pathways	155
4.6	Replication in cell line encyclopaedia	156
4.7	Discussion	158
4.7.1	Strengths of the SLIPT Methodology	158
4.7.2	Synthetic Lethal Pathways for E-cadherin	159
4.7.3	Replication and Validation	161
4.7.3.1	Integration with siRNA Screening	161
4.7.3.2	Replication across Tissues and Cell lines	162
4.8	Summary	163
5	Synthetic Lethal Pathway Structure	166
5.1	Synthetic Lethal Genes in Reactome Pathways	167
5.1.1	The PI3K/AKT Pathway	167
5.1.2	The Extracellular Matrix	169
5.1.3	G Protein Coupled Receptors	172
5.1.4	Gene Regulation and Translation	172
5.2	Network Analysis of Synthetic Lethal Genes	173
5.2.1	Gene Connectivity and Vertex Degree	173
5.2.2	Gene Importance and Centrality	175
5.2.2.1	Information Centrality	175
5.2.2.2	PageRank Centrality	178
5.3	Testing Pathway Structure of Synthetic Lethal Genes	179
5.3.1	Hierarchical Pathway Structure	179
5.3.1.1	Contextual Hierarchy of PI3K	179
5.3.1.2	Testing Contextual Hierarchy of Synthetic Lethal Genes	179
5.3.2	Upstream or Downstream Synthetic Lethality	183
5.3.2.1	Measuring Structure of Candidates within PI3K	183
5.3.2.2	Resampling for Synthetic Lethal Pathway Structure . .	185
5.4	Discussion	186
5.5	Summary	188

6	Simulation and Modeling of Synthetic Lethal Pathways	191
6.1	Comparing methods	192
6.1.1	Performance of SLIPT and χ^2 across Quantiles	193
6.1.1.1	Correlated Query Genes affects Specificity	196
6.1.2	Alternative Synthetic Lethal Detection Strategies	198
6.1.2.1	Correlation for Synthetic Lethal Detection	198
6.1.2.2	Testing for Bimodality with BiSEp	200
6.2	Simulations with Graph Structures	202
6.2.1	Performance over a Graph Structure	203
6.2.1.1	Simple Graph Structures	203
6.2.1.2	Constructed Graph Structures	205
6.2.2	Performance with Inhibitions	209
6.2.3	Synthetic Lethality across Graph Structures	215
6.2.4	Performance within a Simulated Human Genome	219
6.2.4.1	Simple Graph Structures in a Genome	219
6.3	Simulations over pathway-based graphs	224
6.3.1	Pathway Structures in a Simulated Human Genome	227
6.4	Discussion	228
6.5	Summary	228
7	Discussion	228
7.1	Significance	228
7.2	Future Directions	229
7.3	Conclusion	230
8	Conclusion	234

Simulation and Modeling of Synthetic Lethal Pathways

Simulation and modelling of synthetic lethality in gene expression will be revisited in greater detail in this chapter, building upon the results provided to support the use of Synthetic Lethal Interaction Prediction Tool (SLIPT) in Section 3.3. A simulation procedure for generating simulated data with underlying (known) synthetic lethal partners of a query gene, such as *CDH1*, was developed (as described in Section 3.2.2) by sampling from a Multivariate normal distribution based on a statistical model of synthetic lethality in expression data (as described in Section 3.2.1). This simulation framework was applied to simulated data (in Section 3.3), including simple correlation structures to assess the statistical performance of the SLIPT methodology and support its use a computational approach for detecting synthetic lethal candidates from expression data throughout this thesis (in Chapters 4 and 5).

While this basic framework was sufficient to support the use of SLIPT in prior Chapters, further investigations with simulations were conducted to assess the strengths and limitations of the SLIPT methodology, compare it to alternative statistical approaches to synthetic lethal detection, and assess its performance upon more complex correlation structures. Together these simulation investigations assess the performance of the SLIPT methodology, including on pathway graph structures (such as those discussed in Chapter 5) and determine whether the SLIPT methodology (or similar refined bioinformatics strategies) are statistically rigorous or suitable for wider genomics applications.

These simulation investigations continue to utilise the Multivariate Normal simulation procedure (as applied in Section 3.3) with further refinements. The SLIPT methodology (and the equivalent χ^2 test alone) were applied across a range of pa-

rameters (including altering the quantiles for detecting synthetic lethal direction and compared correlation. This was also applied to with query correlated genes (as performed in Section 3.3).

A refined simulation procedure was developed specifically to extend the simulation procedure (described in Section 3.2) to utilise pathway graph structures for the correlation structures of simulated datasets (as described in Section 3.4.2). This methodology can be applied to simulated correlation structures across simple graph structures to test specific network modules or use pathway structures based on biological pathways (as discussed in Chapter 5). Thus graph structure and simulation approaches were combined to test whether a gene locus in a pathway affects detection by SLIPT and whether SLIPT performance is affected by pathway structure. The simulation procedure based on graph structures were applied in a computational pipeline across many parameters with high-performance computing (as discussed in Section 2.5.3) and the core simulation functions have been released as a software package for wider use to test bioinformatics and statistical methods on graph structures (as described in Section 3.5.3).

6.1 Comparing methods

The SLIPT methodology (as it has been applied throughout Chapters 4 and 5) was compared to alternative computational approaches to detecting synthetic lethality in simulated gene expression data. As discussed in Section 3.3, this procedure enables testing the performance of detecting known synthetic lethal partner genes by sampling from a statistical model of synthetic lethality. While comprehensive benchmarking has not been performed, several approaches to synthetic lethal detection are considered (e.g., Pearson’s correlation, the χ^2 test, and testing for bimodality) to evaluate the strengths of the SLIPT methodology, including modifications to the parameters of SLIPT.

Further testing of the performance of the SLIPT software R package (which is publicly released on GitHub as described in Section 3.5) has been left to third party researchers to impartially compare it to other software for synthetic lethal detection which is outside the scope of this thesis. The following comparisons of simulations of computational detection of synthetic lethality with different statistical rationales suffice to discuss the strengths of SLIPT, evaluate whether it is appropriate for further application in genomics research, and identify limitations which may be addressed

with further developments. Some potential avenues for further development of computational synthetic lethal discovery will be discussed in Section 7.2.

6.1.1 Performance of SLIPT and χ^2 across Quantiles

Simulated datasets with synthetic lethal partner genes were generated using the multivariate normal simulation procedure (as described in Section 3.2.2) with performance assessed using area under the receiver operating characteristic (AUROC) analysis (as described in Section 2.3.5). Synthetic lethal detection was compared for modifications to the SLIPT methodology (as described in Section 3.1), namely that the quantiles used to define low and high expression was varied. Rather than $\frac{1}{3}$ (as used throughout this thesis) the samples below the lowest $\frac{1}{n}$ quantile and above the highest $\frac{1}{n}$ quantile were used for SLIPT (and the χ^2 -test) to detect lowly and highly expressing samples respectively. The quantiles tested range from 2, splitting at the $\frac{1}{2}$ quantile (the median), to 100, using the lowest (1%) and highest (99%) percentiles.

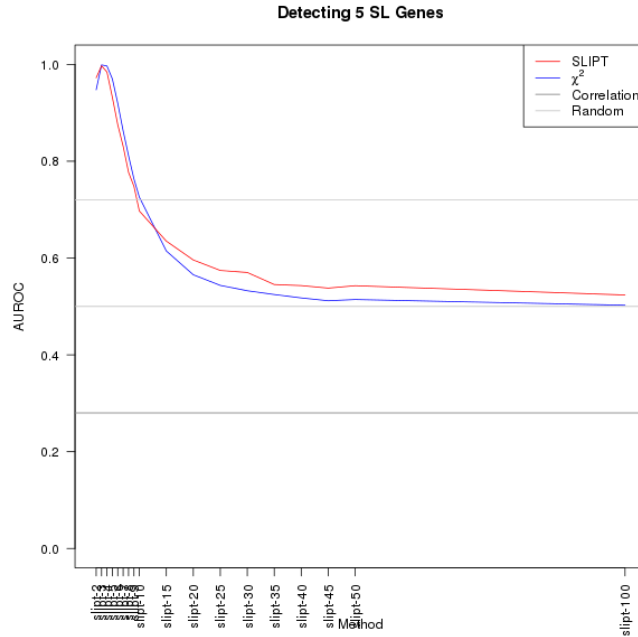

This enables testing of the threshold for lowly expressing genes which is most able to distinguish synthetic lethal genes, even with higher-order synthetic lethal interactions (as discussed in Section 3.2.1). Both SLIPT with the directional criteria for synthetic lethality and significance of the equivalent χ^2 test were performed for each quantile. Pearson’s correlation was also tested on simulated continuous expression data for synthetic lethal detection in simulated data, considering both positive and negative correlations separately as predictors of synthetic lethality for comparison with χ^2 based approaches, using discrete categories for gene function deriving from quantiles.

The results presented throughout this section use the example of 5 synthetic lethal partners to illustrate the differences in performance between the standard SLIPT procedure (slipt-3) to n quantiles (slipt- n), the χ^2 -test on the same quantiles, and positive or negative correlation. However, similar results across different numbers of known synthetic lethal genes are shown in Appendix N. The synthetic lethal detection procedures were compared with 10,000 simulations of a small dataset of 100 genes and 1000 samples without correlation structure between genes as performed in Section 3.3.2). As shown in Figure 6.1, the 3-quantiles previously used have optimal performance and SLIPT has a comparable or higher performance than the χ^2 -test alone across quantiles.

Pearson’s correlation performed worse than random (with an AUROC lower than 0.5) as thus coexpression of genes is not predictive of synthetic lethality in simulated data. Conversely, negative correlation is predictive of synthetic lethality, consistent with synthetic lethal gene activity being mutually exclusive. However, neither correla-

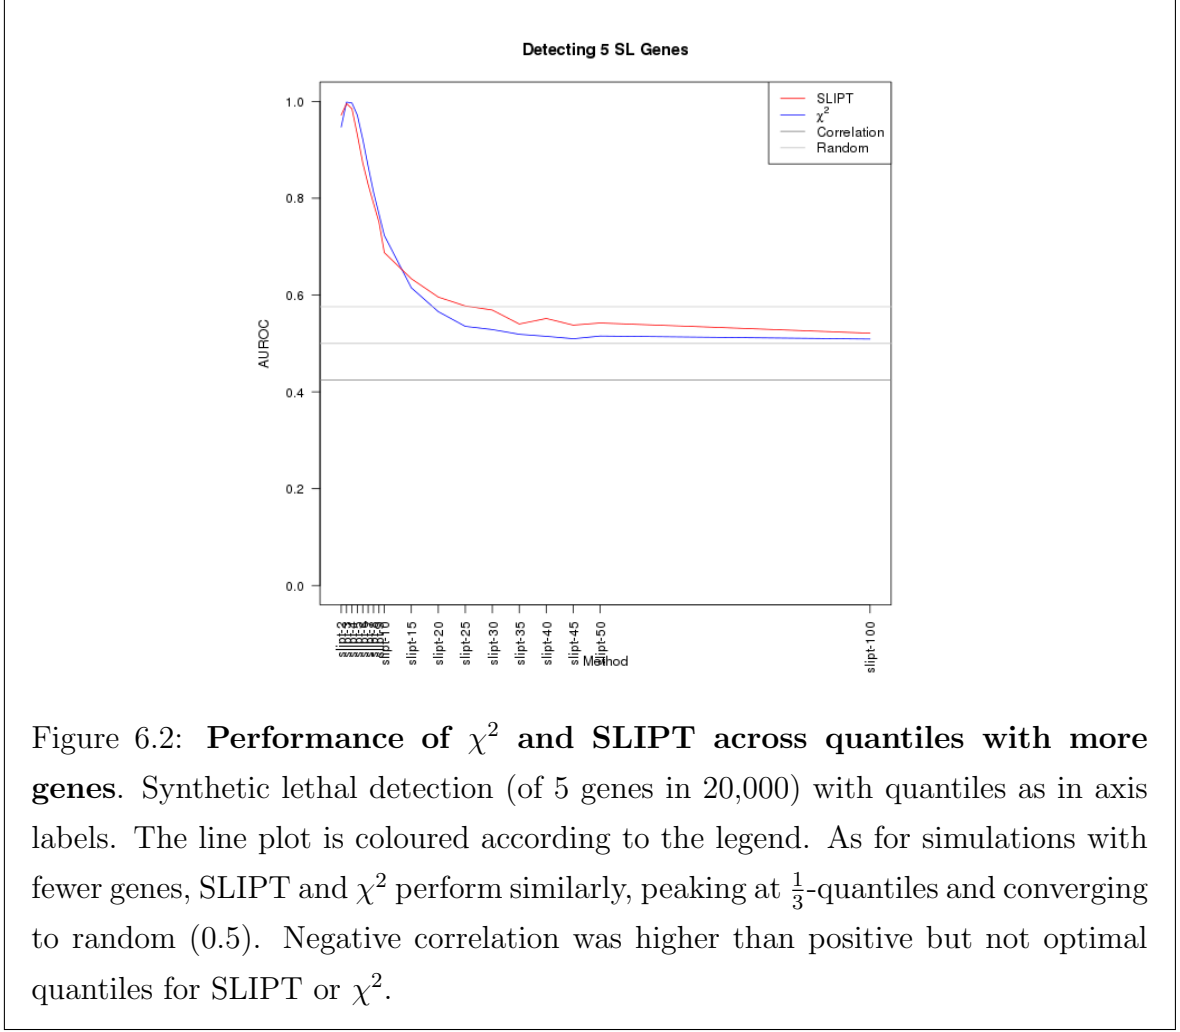

(a) Barplot of χ^2 , SLIPT, and correlation.

(b) Lineplot of χ^2 , SLIPT, and correlation.

Figure 6.1: **Performance of χ^2 and SLIPT across quantiles.** Synthetic lethal detection (of 5 genes) with quantiles as in axis labels. The barplot uses the same hues for each quantile (grey for correlation) and darker for χ^2 (and positive correlation). The line plot is coloured according to the legend. SLIPT and χ^2 perform similarly, peaking at $\frac{1}{3}$ -quantiles and converging to random (0.5). Negative correlation was higher than positive but not optimal quantiles for SLIPT or χ^2 .

tion approach performed as well as the optimal quantiles for the SLIPT procedure or χ^2 -test.

These results are shown in both a bargraph and lineplot to show the individual results of each parameter and compare SLIPT with the χ^2 -test side-by-side across quantiles. Similarly, these plots are given for detecting a range of known synthetic lethal partners in the simulations in Figures N.1 and N.2. These demonstrate that the findings shown for 5 synthetic lethal genes is robust across different numbers of underlying synthetic lethal genes.

The synthetic lethal detection procedures were also tested with 1000 simulations of a larger dataset of 20,000 genes and 1000 samples. While fewer simulations gives a less accurate receiver operating characteristic (ROC) result, this is sufficient to replicate the above findings with a feasible human of genes in a human gene expression dataset and assess the impact of a higher proportion of non synthetic lethal genes (potential

false positives). Simulated datasets of this size were also used in Section 3.3.2 to test the specificity in a number of genes similar to that in experimental datasets for cancer genomes. As shown in Figure 6.2, the above findings were replicated in simulations of a larger dataset with 20,000 genes. These were also robustly replicated across varying numbers of underlying synthetic lethal genes (as shown in Figure N.3).

6.1.1.1 Correlated Query Genes affects Specificity

As discussed in Section 3.3.2.2, positively correlated genes (with the query gene) have an impact of on the performance of synthetic lethal detection. SLIPT able to distinguish these from synthetic lethal partners and hence has a higher specificity in datasets which include positively correlated genes with the query gene (as expected in gene expression data). The synthetic lethal detection procedures were compared with 10,000 simulations of a small dataset of 100 genes (with 5 correlated with the query gene) and 1000 samples otherwise without correlation structure between genes. As shown in

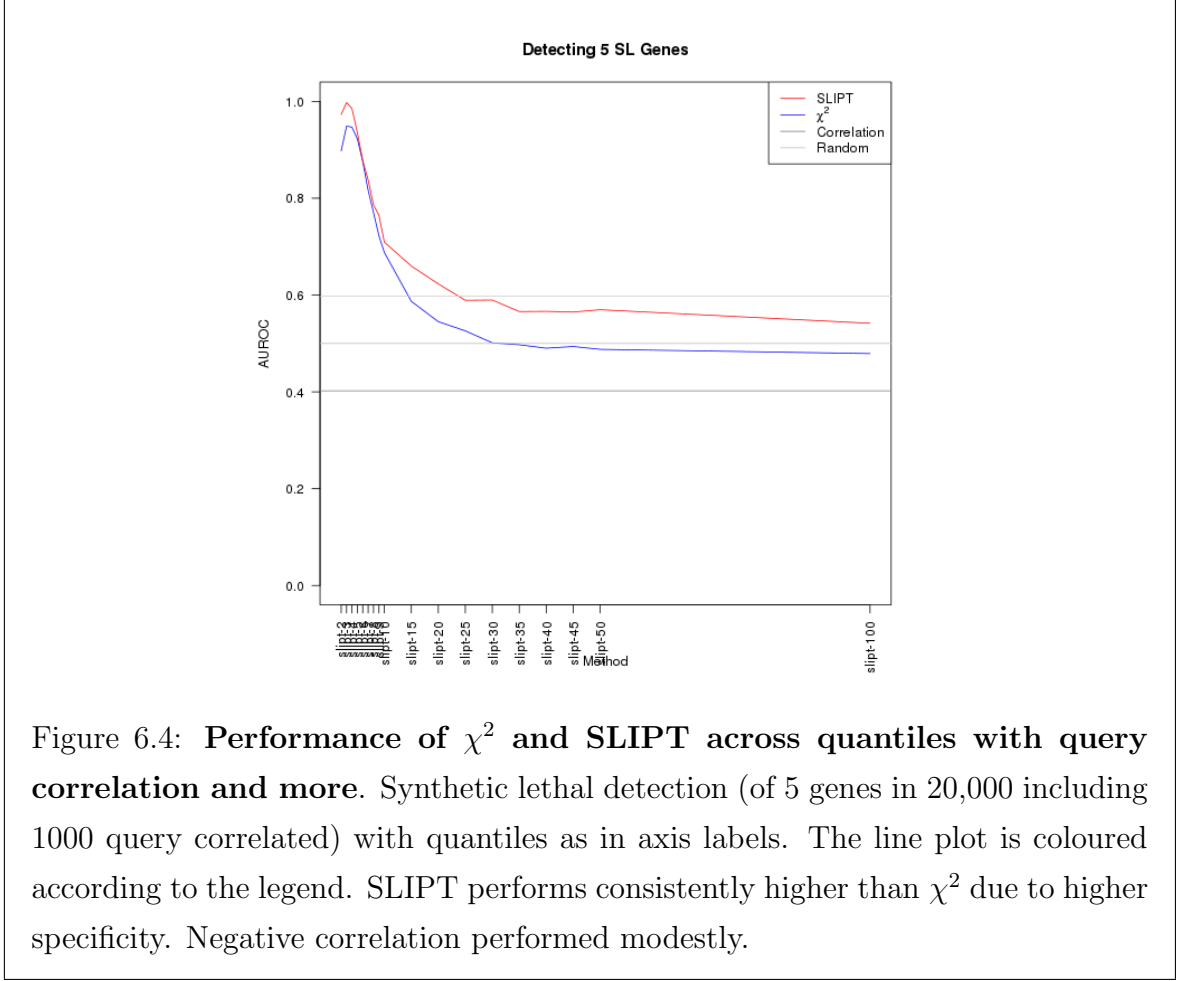

Figure 6.3, this specificity is reflected in the increased AUROC performance values for SLIPT (in contrast to Figure 6.1). This specificity can be attributed to the directional criteria (as described in Section 3.1) since the χ^2 -test alone performs comparatively poorly with positively correlated genes.

The synthetic lethal detection procedures were also compared with 1000 simulations of a larger dataset of 20,000 genes (with 1000 correlated with the query gene) and 1000 samples otherwise without correlation structure between genes. This simulation increases the number of genes (and proportion of negative genes) to those feasible in a human gene expression dataset while maintaining a comparable 5% of positively correlated genes. As shown in Figure 6.4, SLIPT still outperforms χ^2 or negative correlation and is optimal at the 3-quantile. However, the difference between SLIPT and χ^2 were less pronounced in a larger dataset since the sheer number of negative genes (as potential false positives) affects the specificity of SLIPT which distinguishes it from χ^2 -test alone and is an important consideration in large-scale genomics analysis.

Nevertheless, SLIPT with 3-quantiles (as performed throughout Chapters 4 and 5), has higher performance than other quantiles, particularly with positive correlations (replicating the Section 3.3.2.2). These findings hold across different numbers of underlying synthetic lethal genes (as shown in Figures N.5 and N.6).

Together these results support the use of SLIPT, particularly the use of quantiles as thresholds for gene function and specific use of 3-quantiles which perform well compared to other quantiles. A particular concern in the design of SLIPT for expression data was sufficient sample size when the data is divided into quantiles. The SLIPT methodology further performs better for 3-quantiles (and other moderate values), irrespective of sample size or p-value threshold as AUROC values are independent from them. Such quantiles ensure that there are a sufficient number of samples expected below and above them so that deviations from these are statistically detectable. These quantiles were also optimal for the χ^2 as both significance and the SLIPT directional conditions rely use the same expected values.

6.1.2 Alternative Synthetic Lethal Detection Strategies

The categorical approach for gene function to detect synthetic lethality also outperforms correlations which use continuous data directly. Correlation performing poorly as a synthetic lethal detection strategy consistent with there not necessarily being a relationship between synthetic lethal partners which can be in distinct biological pathways, expressed at different times or in different cell types. Nevertheless, correlation is among the alternative detection methods considered in further detail.

The BImodal Subsetting ExPression (BiSEp) R package (Wappett, 2014) for using bimodality to detect synthetic lethality (Wappett *et al.*, 2016) and linear models were also considered. These statistical methods span a range of computational approaches to detecting synthetic lethality and serve to compare alternatives to SLIPT, supporting its design (see Section 3.1) and application (in Chapters 4 and 5). Although these are intended not intended to be a comprehensive benchmarking of existing synthetic lethal tools, implementing other synthetic lethal detection software is out of the scope of this project. However, these comparisons are able provide supporting data from statistical modelling and simulations for the viability of the SLIPT methodology for synthetic lethal discovery in cancer (as demonstrated in Chapter 4) and further applications.

6.1.2.1 Correlation for Synthetic Lethal Detection

As shown in Section 6.1.1, negative (Pearson's) correlation performed better than positive correlation, indicating the inverse relationships were more predictive of synthetic

lethality. However, neither correlation approach performed as well as SLIPT or the χ^2 test as a predictor of synthetic lethal gene partners. Although negative correlation still often performed considerably better than random chance.

Figure 6.5: **Performance of negative correlation and SLIPT.** Synthetic lethal detection with SLIPT was compared to negative (Pearson’s) correlation across parameters. SLIPT consistently outperformed correlation, although both approaches had lower performance for more synthetic lethal partners and lower sample sizes.

Negative correlation was compared directly to the SLIPT methodology (as described in Section 3.1) across numbers of known synthetic lethal partners and sample size (ranging from 500 to 5000). This comparison used 1000 simulations of a dataset

with 20,000 genes and synthetic lethal genes from within a network (sampled as in Section 3.4.2)) with a 0.8 correlation between adjacent genes (as explored in more detail in Section 6.2). In a direct comparison of SLIPT and negative correlation (shown in Figure 6.5), SLIPT consistently has higher performance in simulated data across parameter values and (inverse) correlation-based approaches perform modestly in comparison.

[Add Other Graphs to Appendix?]

Both SLIPT and correlation had poorer performance with increasing numbers of the synthetic lethal genes to detect while they had higher performance in higher sample sizes as expected (as previously observed for SLIPT in Section 3.3). Thus the issue with detection of greater numbers of synthetic lethal genes is not specific to SLIPT but occurs across computational methods of synthetic lethal discovery in (simulated) expression data and likely stems from cryptic higher-order synthetic lethal interactions (as conservatively assumed in Section 3.2.1).

6.1.2.2 Testing for Bimodality with BiSEp

Exhaustive attempts were also made to compare SLIPT to the BiSEp methodology (Wappett *et al.*, 2016), a statistical approach to identify synthetic lethal gene pairs from mutually exclusive relationships using bimodal distributions. This synthetic lethal detection methodology is also designed for expression analysis in cancer and is readily available as an (open-source) R package (Wappett, 2014), a practice which facilitates adoption and testing of the methodology on the same datasets and simulations procedures as previously used for SLIPT.

The BiSEp package is designed for global testing of all potential gene pairs in the genome for synthetic lethality rather than focusing on the search space of potential partners of the query gene. This approach was unable to detect synthetic lethal gene pairs in the TCGA breast cancer expression dataset (TCGA, 2012). However, this may be due to stringent thresholds under the multiple testing of millions of potential gene pairs.

For a direct comparison with the query-based SLIPT approach, the source code of the BiSEp R functions were modified to test solely for the partners of a specific gene. This approach was still unable to detect synthetic lethal partners of *CDH1* in TCGA breast cancer expression data (TCGA, 2012), even with the detection thresholds for bimodality and significance greatly relaxed from those which the package defaults to.

To circumvent multiple testing issues, BiSEp only tests gene pairs for synthetic lethality between genes with a detectable bimodal distribution. However, even with relaxed thresholds bimodal distributions were not detectable in the normalised TCGA

data (TCGA, 2012). Such normalisation Ritchie *et al.* (2015) is standard practice for expression datasets generated from microarrays or RNA-Seq and therefore BiSEp may not be appropriate to apply to this data. However, it is noted that BiSEp may also use other data types such as DNA copy number or cell line data for which it may be more applicable Wappett *et al.* (2016).

Nevertheless, attempts were made to test BiSEp on simulated datasets with underlying synthetic lethal genes (using the procedures described in Sections 3.2.2 and 3.4.2). However, BiSEp was also unable to detect genes with bimodal distributions of genes (and thus unable to detect synthetic lethality) in a limited number of simulations. Another consideration is that BiSEp takes considerably more time to compute predictions than SLIPT or χ^2 which limited the number of simulations that were feasible and made it difficult to apply across parameters in the simulation pipeline (even when using supercomputing infrastructure as discussed in Section 2.5.3).

The computationally intensive nature of the BiSEp procedure does not appear to be the issue for detecting synthetic lethal genes in TCGA data or simulations, although it has made more extensive simulations challenging. Rather BiSEp is not suitable in either case since the TCGA data is normalised with voom (Ritchie *et al.*, 2015) and simulated data is generated by sampling from a multivariate normal distribution. In either case, even subtle bimodal signatures in expression data were not consistently detectable or sufficient to detect synthetic lethality. The BiSEp methodology may perform better on other data types but it cannot be directly compared with the results for SLIPT throughout this thesis which have used normalised or (multivariate) normally distributed data. Since it requires bimodal distributions, BiSEp is not suitable for stringently normalised expression data nor would it be expected to perform on (ranked) pathway metagenes. Thus SLIPT represents a distinct approach more suitable for these data types whereas BiSEp may be applicable to other applications in which bimodal distributions are more frequent.

This investigation also demonstrates that implementing scientific software from other research groups is not a trivial exercise, even when released as an open-source R package. Therefore, the above results are sufficient to evaluate SLIPT and compare it to other statistical rationales. An comprehensive comparison to contemporary synthetic lethal detection approaches (and those released in the future) or further benchmarking is left to an impartial researcher to evaluate and is outside the scope of this thesis. The above findings show that the SLIPT approach is able to detect synthetic lethal

genes in simulated data with comparable or better performance than a range of distinct statistical techniques and was appropriate for use throughout this thesis.

[Compare runtime?]

[Discuss linear models?]

6.2 Simulations with Graph Structures

Simulations of synthetic lethality in Section 3.3 included correlated blocks of genes as a rudimentary model of pathway structure and co-regulated genes. Here the simulation procedure was expanded to account for more complex graph structures by sampling from multivariate normal distributions with correlation structure derived from graph structures (as described in Section 3.4.2). This approach enables simulation of synthetic lethal pathways with known correlation structure and known partners (of a gene not in the pathway) and evaluation of the performance of SLIPT under simple controlled correlation structures and complex correlations such as those derived from biological networks (such as those described in Chapter 5). The SLIPT methodology will be tested both in artificial constructed networks to evaluate the effect of pathway structure on synthetic lethal detection and on large biologically feasible pathways to test whether SLIPT is robust under complex correlation structures and applicable to such complex genomics data.

These simulations combine the approach of prior simulation analyses (in Sections 3.3 and 6.1) with the graph structures for biological pathways (as used in Chapter 5). This enables testing whether subtle or large differences in pathway structure affect synthetic lethal detection, whether inhibiting relationships (or inverse correlations) between genes affects synthetic lethal detection, and whether synthetic lethal detection varies across which gene is synthetic lethal or affects proximal genes in the pathway structure. In addition, large numbers of synthetic lethal genes and biologically feasible numbers of genes (with many non-synthetic lethal genes) will be tested to replicate the findings of Sections 3.3 and 6.1 in correlated structures derived from pathway graphs, including examples of biological pathways from Reactome.

To demonstrate the impact of pathway structure on the performance of SLIPT for synthetic lethal detection in simulations, simple and more complex constructed graph structures will be used (as depicted in Figures O.1–O.6). In addition, the phosphoinositide 3-kinase (PI3K) and $G_{\alpha i}$ signalling pathways derived from Reactome will be used for simulation of pathway structures of biological complexity (as shown in Figures 5.1 and J.4).

6.2.1 Performance over a Graph Structure

6.2.1.1 Simple Graph Structures

Simple pathway modules were used to test the effect of pathway structure on the performance of detecting synthetic lethal partners within graph structures. To start with, the cases (shown by Figure O.1) where a gene has one upstream regulator and two downstream (Graph1) or a gene has two upstream regulators and one downstream gene (Graph2) were used. In these simulations, SLIPT has a high performance detecting randomly selected synthetic lethal partners in small simple networks (as shown in Figures 6.6 and O.7).

As previously observed (in Section 3.3), performance declines with higher numbers of synthetic lethal genes to detect and lower sample sizes. Although the sensitivity of SLIPT is high with conventional p-value thresholds (adjusted by FDR). Thus synthetic lethal partners are often distinguishable for non synthetic lethal genes, even in simple highly correlated networks. The small number of genes and their high correlation has an impact on the ROC curves for higher numbers of synthetic lethal partners which are skewed compared to those observed previously. Note that specificity cannot be tested if all genes potential partner genes are synthetic lethal which limits the number of synthetic lethal genes which can be tested.

These results are particularly consistent between the pathway modules of diverging (Graph1) and converging (Graph2) signals, with the AUROC performance and underlying curves being strikingly similar between these graph structures (as shown in Figures 6.6 and O.7). This indicates that the performance of SLIPT is not perturbed by pathway structure, in particular the direction of pathway relationships as these graph structures also demonstrate pathways in opposite direction. In a direct comparison (shown in Figure 6.7), the performance of simulations in these simple graphs does not differ across parameter values and therefore SLIPT is robust to pathway direction.

(c) Graph Structure

(d) Statistical performance

Figure 6.6: **Performance of simulations on a simple graph.** Simulation of synthetic lethality was performed sampling from a multivariate normal distribution generated from Graph1. Performance of SLIPT declines for more synthetic partners but this is mitigated by increased sample sizes (in darker colours). This manifests as a decline in specificity and the false discovery rate. For each parameter value, 10,000 simulations were used.

(c) Gene category in simulations

Figure 6.7: **Performance of simulations is similar in simple graphs.** The AUROC values for simulations of multivariate normal distributions based on each Graph structure yielded indistinguishable performance across parameter values in 10,000 simulations.

6.2.1.2 Constructed Graph Structures

Progressively more complex graph structures were used to test the performance detecting synthetic lethal partners with SLIPT in simulated expression data with pathway correlation structures. For simple chains of gene representing pathways (shown in Figures O.8 and 6.8), the above findings were generally replicated. Performance was high across parameter values in these small networks, with similar decreases in higher numbers of synthetic lethal genes to detect and lower sample size.

(a) Statistical evaluation

(b) Receiver operating characteristic

(c) Graph Structure

(d) Statistical performance

Figure 6.8: Performance of simulations on a constructed graph. Simulation of synthetic lethality was performed sampling from a multivariate normal distribution generated from Graph4. Performance of SLIPT declines for more synthetic partners and lower sample sizes. For each parameter value, 10,000 simulations were used.

When detecting synthetic lethal genes with SLIPT using adjusted (FDR) p-value thresholds, the performance differences can be largely attributed to changes in specificity. Although the accuracy increases and false discovery rate decreases desirably with higher numbers of synthetic lethal genes despite a lower performance in ROC curves. Therefore the thresholds imposed by adjusted p-values are appropriate for detecting synthetic lethal partners, even in strongly correlated pathways, at least in these small-scale test cases.

However, an artifact of these small test cases is the skewed ROC curves (as discussed in Section 6.2.1.1) which may be related to the low number of non-synthetic lethal genes to identify as true negatives, affecting the accuracy of specificity. This is unlikely to occur in large expression datasets with many negative genes, as shown previously (in Section 3.3) and 6.2.1.1) in simulations of graphs structures in larger datasets (in Section 6.2.4). This does not occur in larger, more complex graphs structures, even with modest total numbers of genes and high correlations.

As shown in Figure 6.9, sensitivity declines over a greater range for the number of synthetic lethal partners in a larger network with a tradeoff with specificity. Although the accuracy declines for greater numbers of synthetic lethal partners and the false discovery rate peaks at intermediate values. In this range difference between simulations with greater sample size. The AUROC results were similar for other more complex graph structures (as shown in Figures O.9 and O.10), these graphs performed similarly to each other, although they had differences from Figure 6.9 in their sensitivity and specificity at an adjusted (FDR) p-value threshold. This difference may stem from different ratios of synthetic lethal and non-synthetic lethal genes to detect, since the latter graphs (in Figures O.9 and O.10) had half the total genes to that shown in Figure 6.9.

However, the graph structures (of similar size) were highly distinct and yet had similar performance profiles across parameters. Therefore SLIPT is robust across pathway structures and is more affected by the number of genes to detect and their proportion in those tested and the findings from previous simulations in similar correlation structures (in Section 3.3) should be applicable to expression data with more complex correlation structures such as biological data containing biological pathways. Specifically, synthetic lethal partners are distinguishable from closely correlated genes in the context of a biological pathway network both irrespective of thresholds (shown by ROC) and with the sensitivity and specificity of p-value thresholds (adjusted by FDR) as used for SLIPT (in Chapters 4 and 5).

(a) Statistical evaluation (b) Receiver operating characteristic

(c) Graph Structure

(d) Statistical performance

Figure 6.9: **Performance of simulations on a large graph.** Simulation of synthetic lethality was performed sampling from a multivariate normal distribution generated from Graph5. Performance of SLIPT declines for more synthetic partners and lower sample sizes. For each parameter value, 10,000 simulations were used.

6.2.2 Performance with Inhibitions

Simulations of synthetic lethality in expression data was also performed with correlation structures derived from graph structures with inhibiting relationships (as are commonplace in biological pathways) which produce negative correlations. As shown in Figure 6.10, these are not an issue for detection by SLIPT. Rather the SLIPT procedure performs well on simple graph modules with highly negative correlations. In particular, these have higher specificity and accuracy with a lower false discovery rate with p-value (adjusted by FDR) detection thresholds compared with the same graph module with (positive correlations) activating relationships (as shown by Figure 6.6).

The ROC curves for an inhibiting graph also show consistently high specificity irrespective of detection threshold with only the upper extreme of the curve exhibiting a skew below random performance (in Figure 6.10). Nevertheless, the AUROC values show a high performance across parameter values, particularly avoiding issues with higher numbers of synthetic lethal partners (as observed in Section 6.2.1.1). Although performance was marginally suboptimal for higher numbers of synthetic lethal genes to detect and lower sample sizes, consistent with previously observations.

Negatively correlated simulated datasets are also unperturbed by minor differences in graph structure, such as changing in the direction of the graph module. As observed for activating relationships in these graph modules, the performance was highly concordant between the graph modules (shown by similar results in Figures 6.10 and O.11).

Detection of synthetic lethality by SLIPT in simulated data with inhibiting relationships outperforms simulations with activating relationships in the same graph structure (as shown in Figure 6.11). Thus SLIPT is robust in gene expression datasets with inverse correlations and performs well in them, at least in simple test cases. This is important because such relationships occur frequently in biological pathways and therefore the findings inferred from graph structures without inhibiting relationships are a conservative estimate.

The SLIPT methodology likely performs better in biological pathways (which contain negative correlations) than the graph structures discussed previously (in Section 6.2.1). This is likely since negative correlations lead to synthetic lethal partners and inversely correlated genes which are positively correlated with the query gene. As previously shown, the SLIPT methodology performs well with specificity against positively correlated query genes (in Sections 3.3.2.2 and 6.1.2.1) and negative correlation with the query gene is a better predictor of synthetic lethality than positive correlation (Sections 6.1.1.1 and 6.1.1), although it still performs worse than SLIPT.

(a) Statistical evaluation

(b) Receiver operating characteristic

(c) Graph Structure

(d) Statistical performance

Figure 6.10: **Performance of simulations on a simple graph with inhibition.** Simulation of synthetic lethality was performed sampling from a multivariate normal distribution generated from Graph2. Performance of SLIPT declines for more synthetic partners and lower sample sizes. For each parameter value, 10,000 simulations were used.

(c) Gene category in simulations

Figure 6.11: **Performance is higher on a simple inhibiting graph.** The AUROC values for simulations of multivariate normal distributions based on inhibitions in the Graph structure yielded consistently higher performance across parameter values in 10,000 simulations.

Similarly, more complex graph structures with entirely inhibiting relationships (negative correlations) also perform desirably on p-value (adjusted by FDR) thresholds and have high performance across increasing number of synthetic lethal genes, particularly for sufficiently high sample sizes (as shown by Figures O.12 and O.13). However, this is not necessarily the case for graph structures with a combination of activating and inhibiting relationships (positive and negative correlations). As shown by Figure 6.12,

such as mixed network structure does not necessarily have high performance across parameters as observed for purely inhibiting networks.

Although these still appear to have desirably high sensitivity, high accuracy, and low false discovery rate for detecting more synthetic lethal genes, despite poor specificity. The ROC curves are particularly skewed for high proportions of the network being synthetic lethal and may stem from low numbers of true negative genes to detect (as discussed in Section 6.2.1.1). In a direct comparison of performance (shown in Figure 6.13), the purely inhibiting graph had consistently higher performance than the activating one as observed for simpler graphs (in Figure 6.11).

In contrast, the combination of activating and inhibiting relationships had slightly lower performance across parameters compared to the same graph structure with activating relationships. Therefore correlation structure can impact on the performance of SLIPT in a graph network, in either direction, specifically the addition of negative correlations. Although this may be an artifact of the simulation procedure as synthetic lethal genes from the correlation structure were randomly selected (without regard to their relationships), with the query gene added to ensure that conditions for synthetic lethal relationships are met.

This solution may be suboptimal (i.e., difficult to detect synthetic lethal partners) as inversely correlated synthetic partner genes will be highly expressed in a mutually exclusive manner such that either of them will be compensating for loss of the query gene in most samples, leading to a weak synthetic lethal signature in expression data in this case. Furthermore, this case may not be representative of empirical biological data as synthetic lethal genes are commonly inversely correlated to the query gene (to some extent) and therefore it is unlikely that they are strongly negative correlated with each other, unless they are synthetic lethal partners of each other as well. It is plausible that many synthetic lethal partner genes will serve to separately compensate for the loss of query gene function and be positively correlated with each other. Nonetheless, these simulations are sufficient to demonstrate that correlation structure (particularly negative correlations) have an impact on the detection of synthetic lethality. However, SLIPT is still able to perform well across graphs with different activating and inhibiting relationships and the perturbations in performance are marginal, particularly those reducing performance compared to an activating network.

These findings were replicated with larger more complex graph structures with inhibiting relationships and more synthetic lethal genes to detect (shown in Figures O.14–O.19). In each graph structure, simulations entirely with inhibiting relationships (Figures O.14, O.16,

(a) Statistical evaluation

(b) Receiver operating characteristic

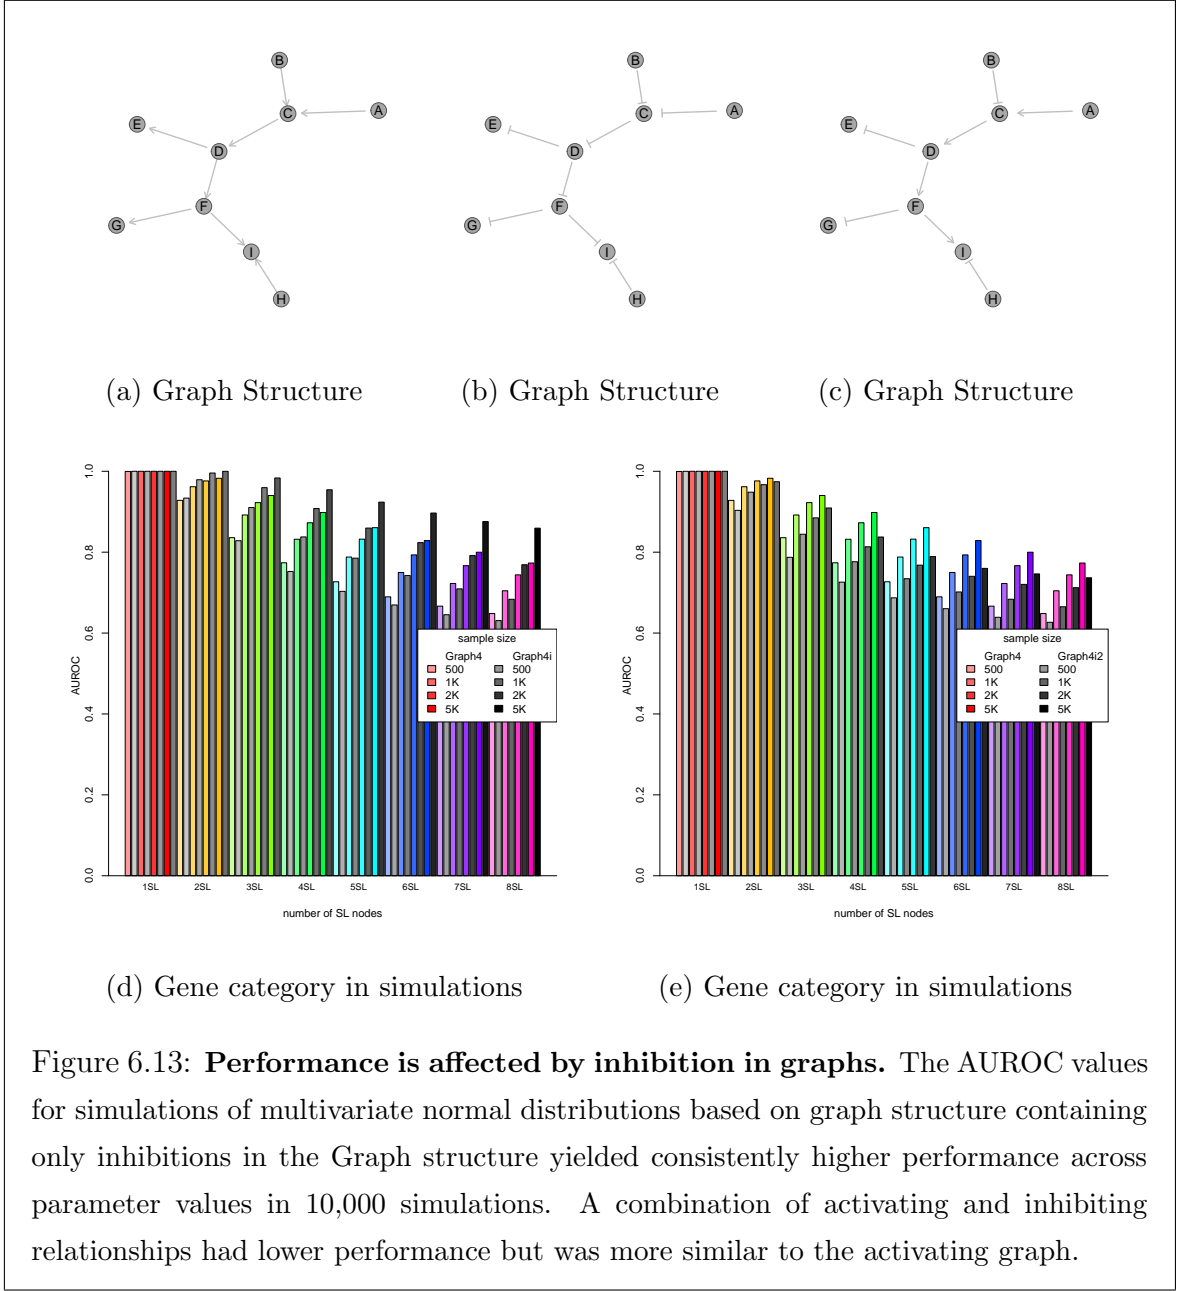

(c) Graph Structure

(d) Statistical performance

Figure 6.12: **Performance of simulations on a constructed graph with inhibition.** Simulation of synthetic lethality was performed sampling from a multivariate normal distribution generated from Graph4 with a combination of inhibitions. Performance of SLIPT declines for more synthetic partners and lower sample sizes. For each parameter value, 10,000 simulations were used.

and O.18) had higher performance than the equivalent graph with entirely activating relationships (Figures 6.9, O.9, and O.10) or a combination of activating and inhibiting relationships (Figures O.15, O.17, and O.19). As previously observed (in Figures O.9 and O.10), the proportion of underlying synthetic lethal genes to detect had a greater impact on performance of detection with SLIPT than the specific structure of the genes which was replicated with inhibiting states (in Figures O.16 and O.18) and combinations with a similar proportion of negative inhibitions (in Figures O.17 and O.19). While the presence of negative correlations subtly affects the performance of SLIPT,

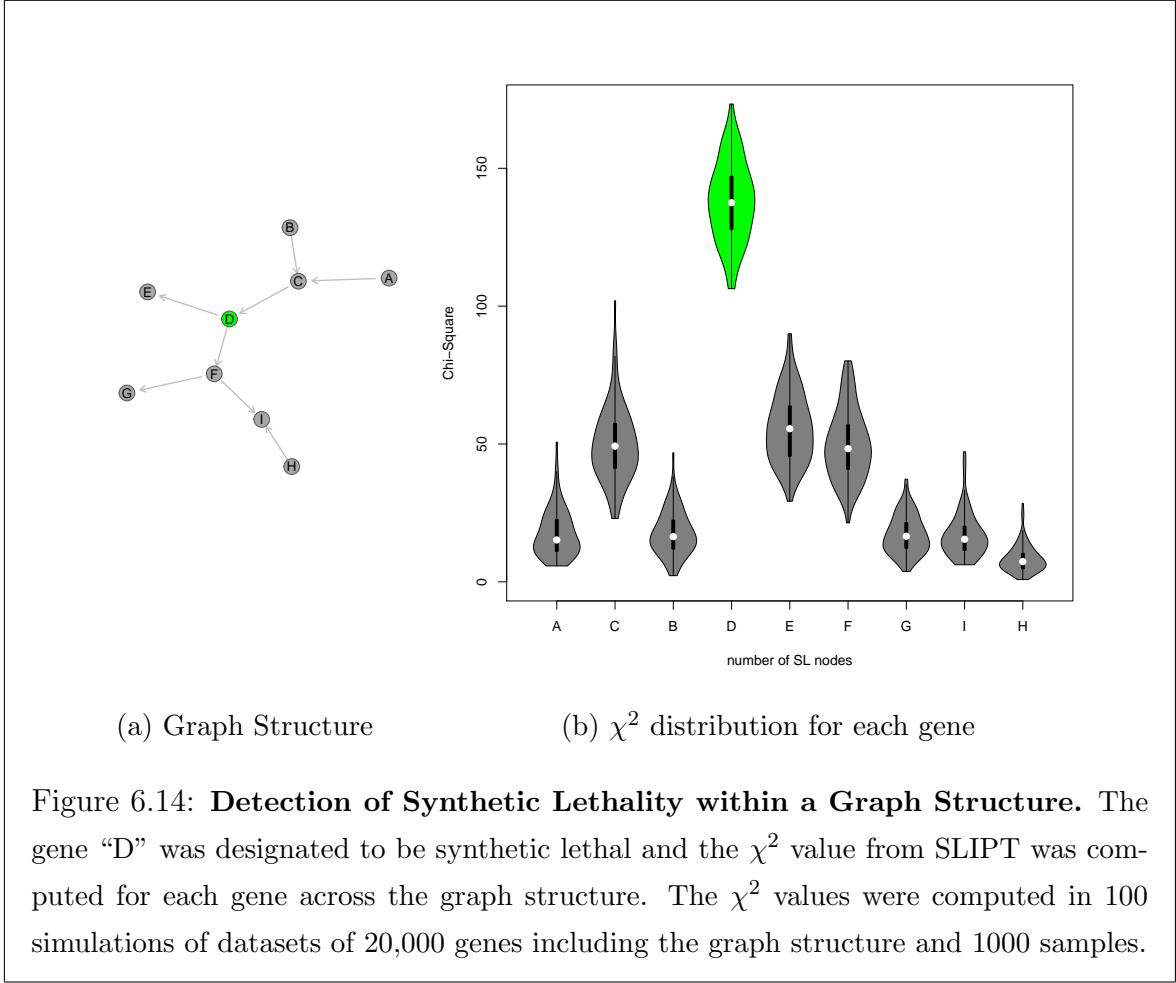

the methodology is robust across the exact structures of genes and is therefore applicable to detecting synthetic lethal genes in a range of (synthetic lethal) biological pathways with different structural relationships.

6.2.3 Synthetic Lethality across Graph Structures

While synthetic lethal genes are distinguishable in principle from those highly positively correlated with them (as shown by ROC analysis), they are not necessarily distinguished as reflected in low specificity and high false discovery rate in poorly performing simulations throughout this section. Although the negative correlations are not subject to the same issue, they sometimes perturb the correlation structure between synthetic lethal partner genes making it difficult to detect many of them. Thus far, synthetic lethal genes have been selected randomly which is a limited approach. To examine the impact of pathway relationships in more detail, specific genes will be selected to be synthetic lethal in a network to demonstrate the impact of these genes being synthetic lethal in the detection of neighbouring genes in the pathway network, under graph structure activating and inhibiting relationships.

For instance, detection of a synthetic lethal genes in an activating graph structure (as shown in Figure 6.14a) is straightforward: the χ^2 values across simulations are clearly distinguishable from non synthetic lethal genes (shown in Figure 6.14b). A small number of simulations were performed for each gene being designated as synthetic lethal. In each case (of each gene being the synthetic lethal partner), the synthetic lethal gene was detectable with highest χ^2 value, being distinguishable amongst 20,000 genes including the highly correlated graph network (as shown in Figure O.20).

This is consistent with previous observations that SLIPT performed optimally for a single synthetic lethal partner in this network (in Figure 6.8). Despite optimal performance in a ROC curve irrespective of detection threshold, many of the highly correlated genes would be detected as false positives using a conventional p-value threshold (even if adjusted by FDR) from a χ^2 test with 4 degrees of freedom as performed by SLIPT (as described in Section 3.1). In particular, the genes that are adjacent to the synthetic lethal gene “D” within the graph structure exhibited high test statistics across simulations which would often be reported as false positives (as shown in Figure 6.14). This is not specific to example of gene “D”, with the neighbouring genes exhibiting higher χ^2 test statistics for each gene in the network when it is designated as the synthetic lethal partner (as shown in Figure O.20).

Thus the synthetic lethal signal propagates from the true synthetic lethal gene throughout the network such genes nearer to the true synthetic lethal gene (more highly correlated) have higher test statistics and are more likely to be detected by SLIPT as false positives. This tendency for adjacent genes to be detected as synthetic lethal false positives is consistent with the synthetic lethal pathways being more concordant between SLIPT in TCGA data (TCGA, 2012) and the short interfering ribonucleic acid (siRNA) screen (Telford *et al.*, 2015) than individual gene results (in Chapter 4). False positive genes are therefore still more likely to be involved in a synthetic lethal pathway by being correlated with a true synthetic lethal gene and synthetic lethal pathways are likely to have many genes detected by SLIPT giving a consensus of evidence, supporting the pathway over-representation approach in particular which may account for how it differs from pathway metagenes. Furthermore, SLIPT is still viable to detect true synthetic lethal partners or prioritise those most likely to be experimentally validated

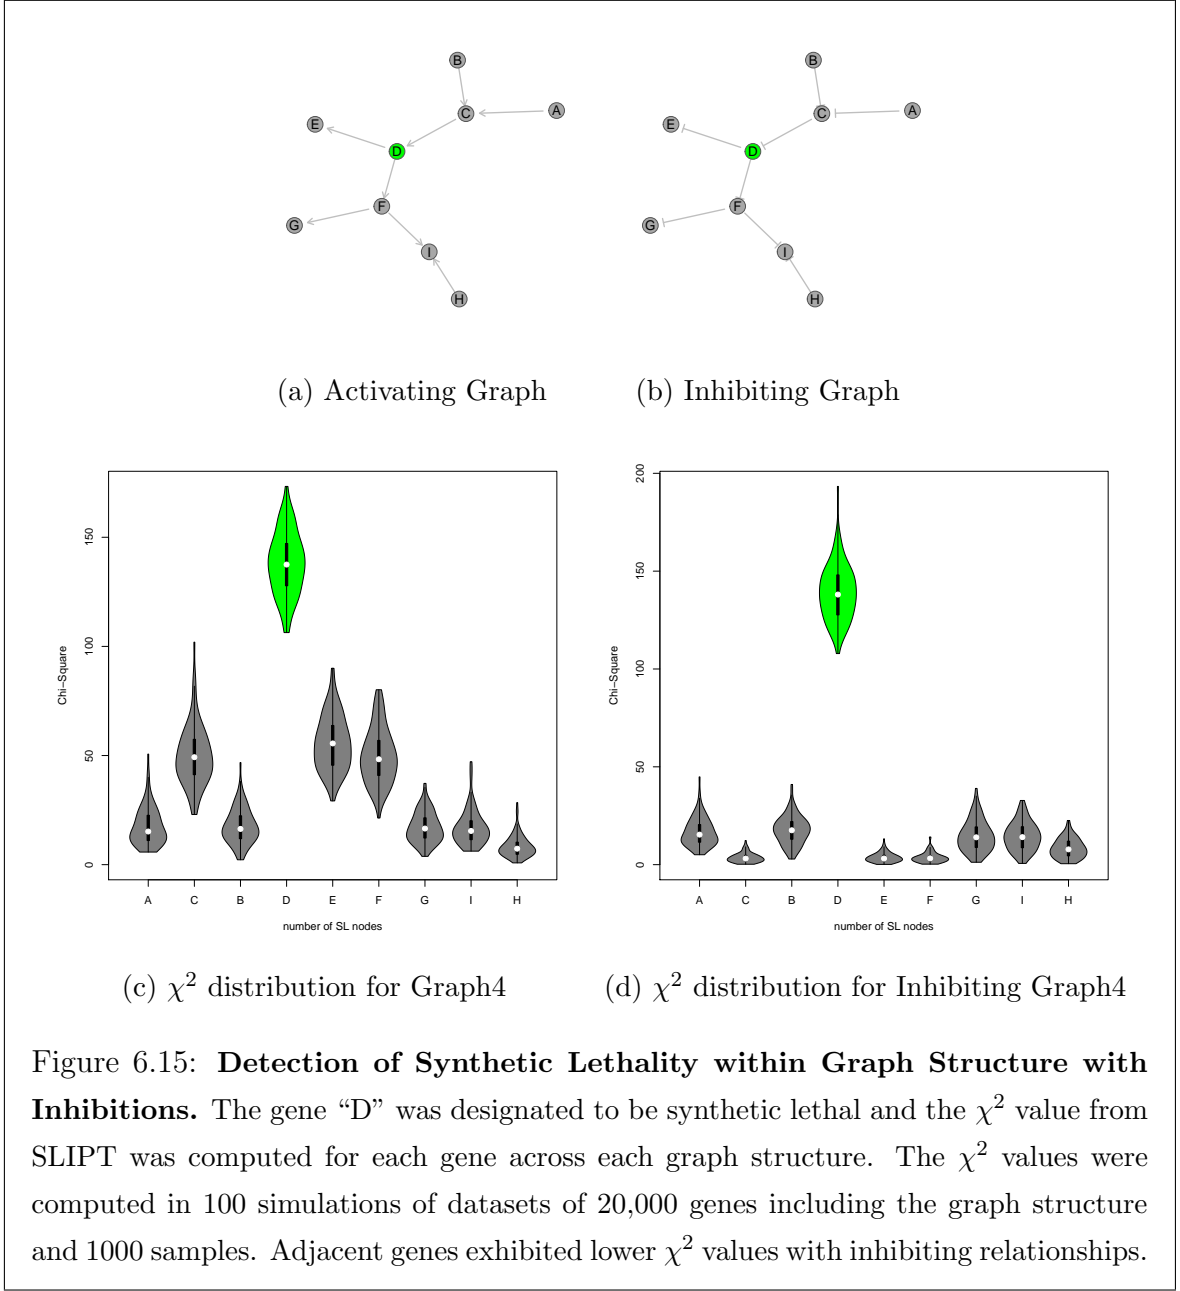

since those with the strongest support (i.e, higher χ^2 values and more significant p-values) are more likely to be the underlying synthetic lethal gene.

In contrast, the immediately adjacent genes did not have elevated χ^2 test statistics indicating synthetic lethality nor a significant inverse effect (as shown in Figure 6.15). Similar simulations were performed a graph structure with inhibiting relationships within a dataset of 20,000 genes. The adjacent genes to the synthetic lethal gene “D” did not have elevated χ^2 values and therefore true synthetic lethal partners were highly distinguishable from non synthetic lethal genes with inhibiting relationships. This was not specific to “D” and was shown across any gene in the graph structure if it were designated to be the synthetic lethal partner of the query gene (shown in Figure O.21). This is consistent with the detection of many genes involved in kinase signalling, gene regulation, and other known cancer pathways (in Chapter 4) which frequently have inhibitory steps. Therefore SLIPT is an appropriate approach to distinguish synthetic lethal partners in biological pathways relevant to cancer growth and inhibition.

However, it should be noted that the 2nd degree neighbours of the synthetic lethal gene still exhibited moderate χ^2 values (and are moderately correlated with the synthetic lethal gene). It is still possible for these to be detected as false positives as previously described for an activating graph structure although the presence of inhibitory relationships (and negative correlations) further increases the differences in test statistics for correlated genes and underlying synthetic lethal partners as shown by the extreme example (in Figure O.21).

These findings are consistent with simulations in a graph containing a combination of activating and inhibiting relationships which exhibits a either of these χ^2 profiles depending on which gene is synthetic lethal and the relationships to adjacent genes (as shown in Figure O.22). Note that in this case, the synthetic lethal gene is distinguishable and inhibitory relationships within this graph structure make it easier to detect underlying synthetic lethal genes with SLIPT by a more highly significant χ^2 test. This contrasts with randomly selecting multiple synthetic lethal genes (in Figure 6.13) where the performance of SLIPT was impeded by the inhibitory relationships between synthetic lethal partners in this graph structure. Therefore the random synthetic lethal genes selected previously with negative correlations between them which had poor performance are likely to have created an artifact in the simulation results as they are biologically implausible and constrain the synthetic lethal simulation procedure

The results with one synthetic lethal partner as sufficient to infer the impact of synthetic lethal partners within pathways on neighbouring (correlated) genes. Although

it is plausible that the synthetic lethal signatures in expression data would propagate through a network with multiple synthetic lethal partners as sources, provided that the correlations between synthetic lethal partners is biological feasible. These simulations were performed on a correlated graph structure within a larger gene expression dataset of 20,000 genes (as performed in Sections 3.3 and 6.2.4), a feasible number for a full human gene expression dataset, and as such are comparable to the findings below.

6.2.4 Performance within a Simulated Human Genome

As noted in Section 6.2.1.1, the high proportion of synthetic lethal partners in small networks made accurately assessing the performance of SLIPT with higher numbers of true partners to detect (and fewer true negatives) difficult. Similarly, adding more true negative genes in previous simulations increased the performance of SLIPT, particularly the specificity to reduce the number of false positives (as shown in Sections 3.3 and 6.1). Building on these findings, here the graph structures (as used in Section 6.2.1) of genes with correlations from sampling a multivariate normal distribution were included in a larger simulated dataset of 20,000 genes. This simulation procedure serves to test the performance of SLIPT at detecting synthetic lethal partners within correlated graph structures (of a synthetic lethal pathway) in the context of biologically feasible numbers of genes.

6.2.4.1 Simple Graph Structures in a Genome

The simulations performed in Section 6.2.1.1 were replicated within a dataset of 20,000 genes with the rest being composed of non synthetic lethal genes without correlation structure. The aforementioned issue with specificity in a higher number of underlying synthetic lethal genes did not occur in a simple graph structure (as shown in Figure 6.16). For such a small graph module of highly correlated genes within a gene expression dataset, detection of synthetic lethal genes within the network by SLIPT and distinguishing these from the larger dataset performed well across parameter values. In this case, a reduction in sensitivity was the cause of poorer performance as a higher number of non synthetic lethal genes were detected as true negative with a low false discovery rate and high accuracy. This further supports the use of stringent χ^2 p-value (adjusted by FDR) thresholds for testing for synthetic lethality in gene expression data across the number of genes in human and cancer data.

In a direct comparison with simulations in the graph structure alone (as performed in Section 6.2.1.1), detection of synthetic lethality with SLIPT performs consistently better in a larger dataset with many true negative genes to detect (as shown in Figure 6.17). This is a desirable property of the SLIPT methodology as it has a high specificity and low false discovery rate. SLIPT is therefore applicable to large gene expression datasets where these are important considerations since the number of negative genes to correctly identify often vastly outnumbers the number of positive genes to detect.

(a) Statistical evaluation

(b) Receiver operating characteristic

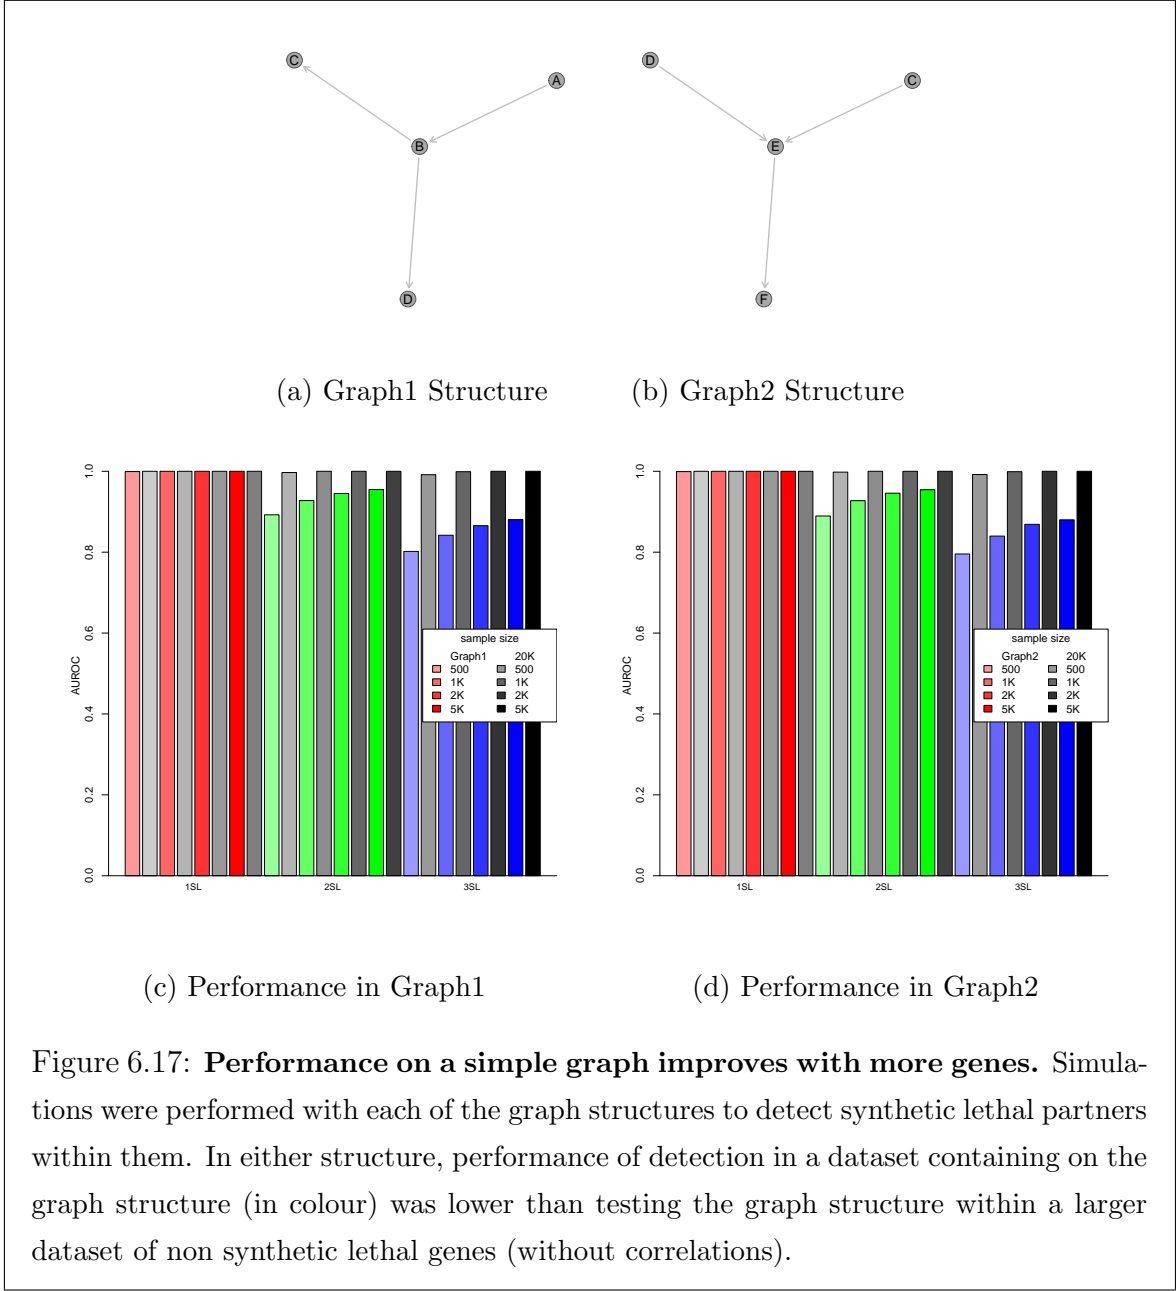

(c) Graph Structure

(d) Statistical performance

Figure 6.16: Performance of simulations including a simple graph. Simulation of synthetic lethality was performed sampling from a multivariate normal distribution (without correlation structure apart from the graph shown). Performance of SLIPT was high across parameters for detecting synthetic lethality in the graph structure within a larger dataset. The sensitivity decreases for a greater number of true positives to detect but the specificity remains high with a low false discovery rate.

This finding was replicated across simple graph modules with similar results between graphs with different directions (as shown in Figure 6.17). Higher performance of synthetic lethal detection in an activating graph structure within the context of a larger gene expression dataset by further replicated across the graph structures presented earlier (as shown in the Appendix by Figures O.23–O.28) and is not specific to the modules shown here.

This increase in performance with more negative genes to detect does not necessarily apply in an inhibiting graph structure. While an increased performance for an

Figure 6.18: Performance on an inhibiting graph with more genes. Simulations were performed in a graph structure with activating and inhibiting relationships to detect synthetic lethal partners within them. In contrast to an activating graph, performance of detection in a dataset containing on the graph structure (in colour) was not lower than testing the graph structure within a larger dataset of non synthetic lethal genes (without correlations) in an inhibiting graph structure with negative correlations.

activating graph was replicated in this case, the performance of simulations of an entirely inhibiting graph structure did not improve within a larger dataset (as shown in Figure 6.18). There is cause for concern since the biological pathways commonly contain inhibiting relationships (and inverse correlations), however, they are rarely as frequent as modelled here. It is reassuring that the performance in the inhibiting graph structure is comparable to simulations of the graph structure in isolation rather than diminished.

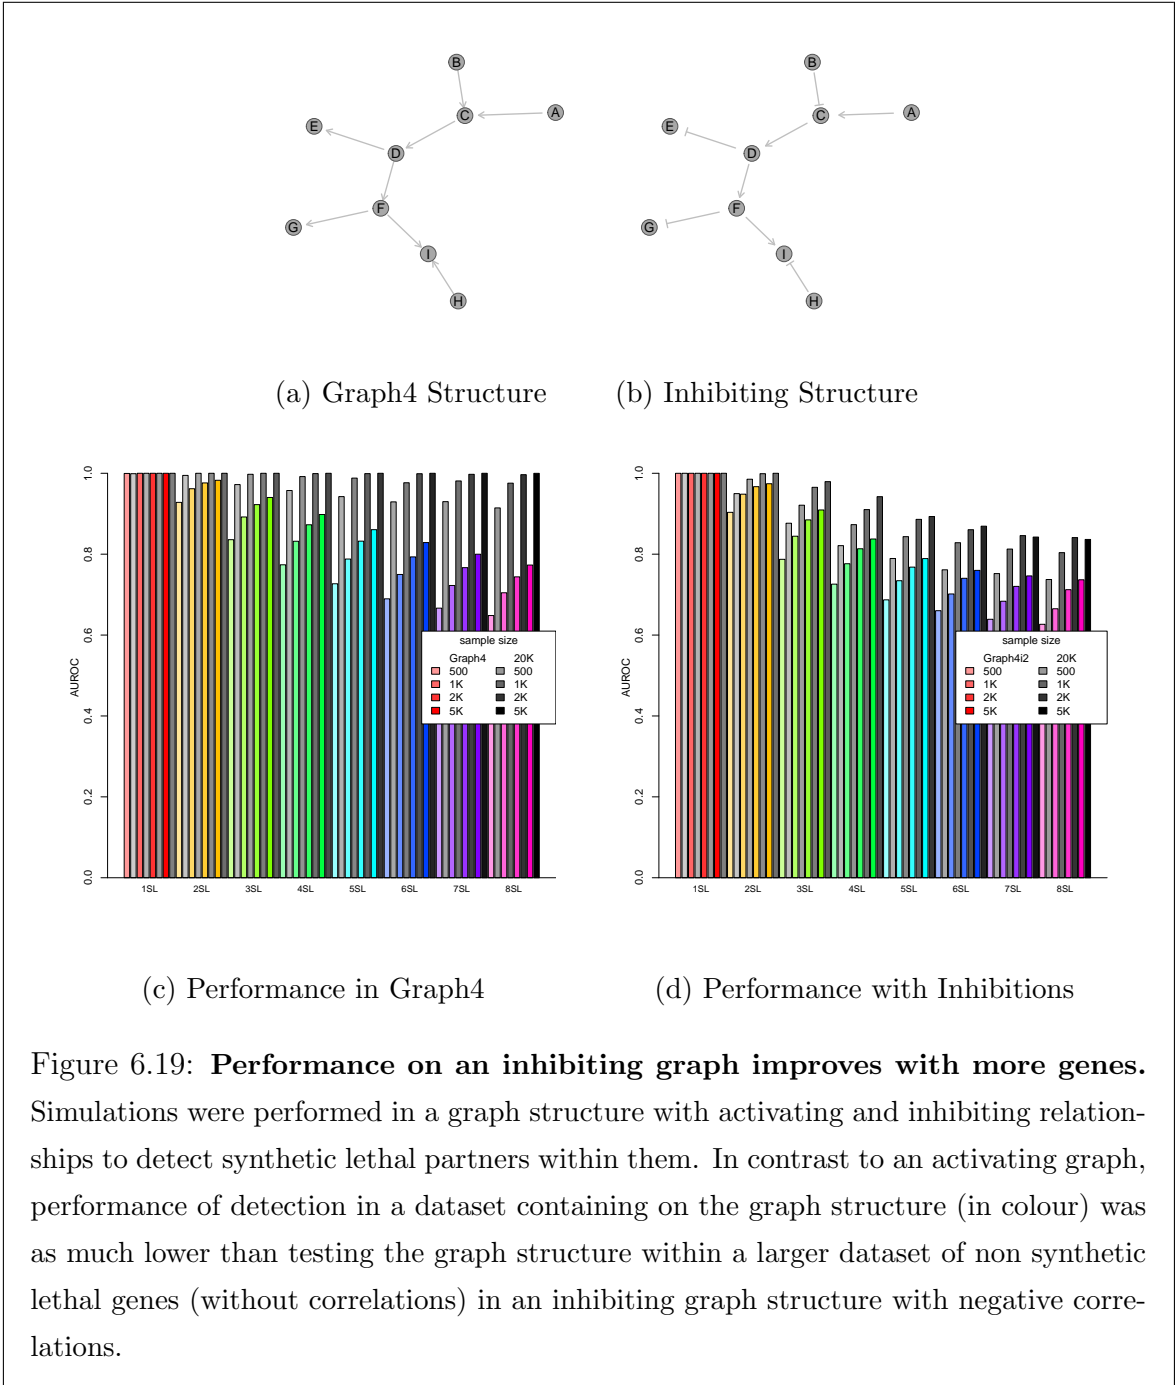

Therefore the findings based on simulations of genes with graph structures in smaller datasets (as described in Section 6.2.1) will be relevant to larger datasets since the simulation results in these perform comparably or higher with more non synthetic lethal genes to distinguish from them even with inhibitory relationships within the graph structure (as shown with supporting results Appendix Figures O.29–O.39). Hence these findings will be relevant in the context of empirical gene expression datasets with thousands of genes such as those in human and cancers.

Performance of synthetic lethal detection of SLIPT in graphs structures with inhibitions included in a larger dataset of non synthetic lethal genes did not necessarily diminish to the level of the graph structure simulated alone. In some cases (as shown in Figure 6.19), the performance of an inhibitory graph structure was consistently elevated when included within a larger data. However, these did not perform as well as the equivalent activating graph structures within a similar dataset.

This poorer performance is unlikely to occur due to highly negatively correlated genes being false positives as they will be positively correlated with the query gene if they are negatively correlated with a synthetic lethal partner (i.e., within a synthetic lethal pathway). The SLIPT procedure performs well at distinguishing these, as previously shown (in Sections 3.3.2.2 and 6.1.1.1). These false positives will also be a minority amongst a larger dataset of non synthetic lethal genes without correlation to the query or synthetic lethal genes.

It more likely that the poorer performance stems from negative correlations between synthetic lethal genes which makes them more difficult to individually detect (as observed in Section 6.2.2). As discussed in Section 6.2.3, this is likely an artifact of the simulation procedure selecting random synthetic lethal genes which may be biologically implausible (such as strong inhibitory relationships between them). Therefore the poorer performing inhibiting graphs within larger datasets are not cause for concern as the cases where SLIPT performs poorly are combinations of simulated synthetic lethal genes which are unlikely to occur within biological pathways. Furthermore the simulation procedure has used included higher-order synthetic lethal to produce the weakest signal of synthetic lethality for individual partner genes and these are still detectable by SLIPT.

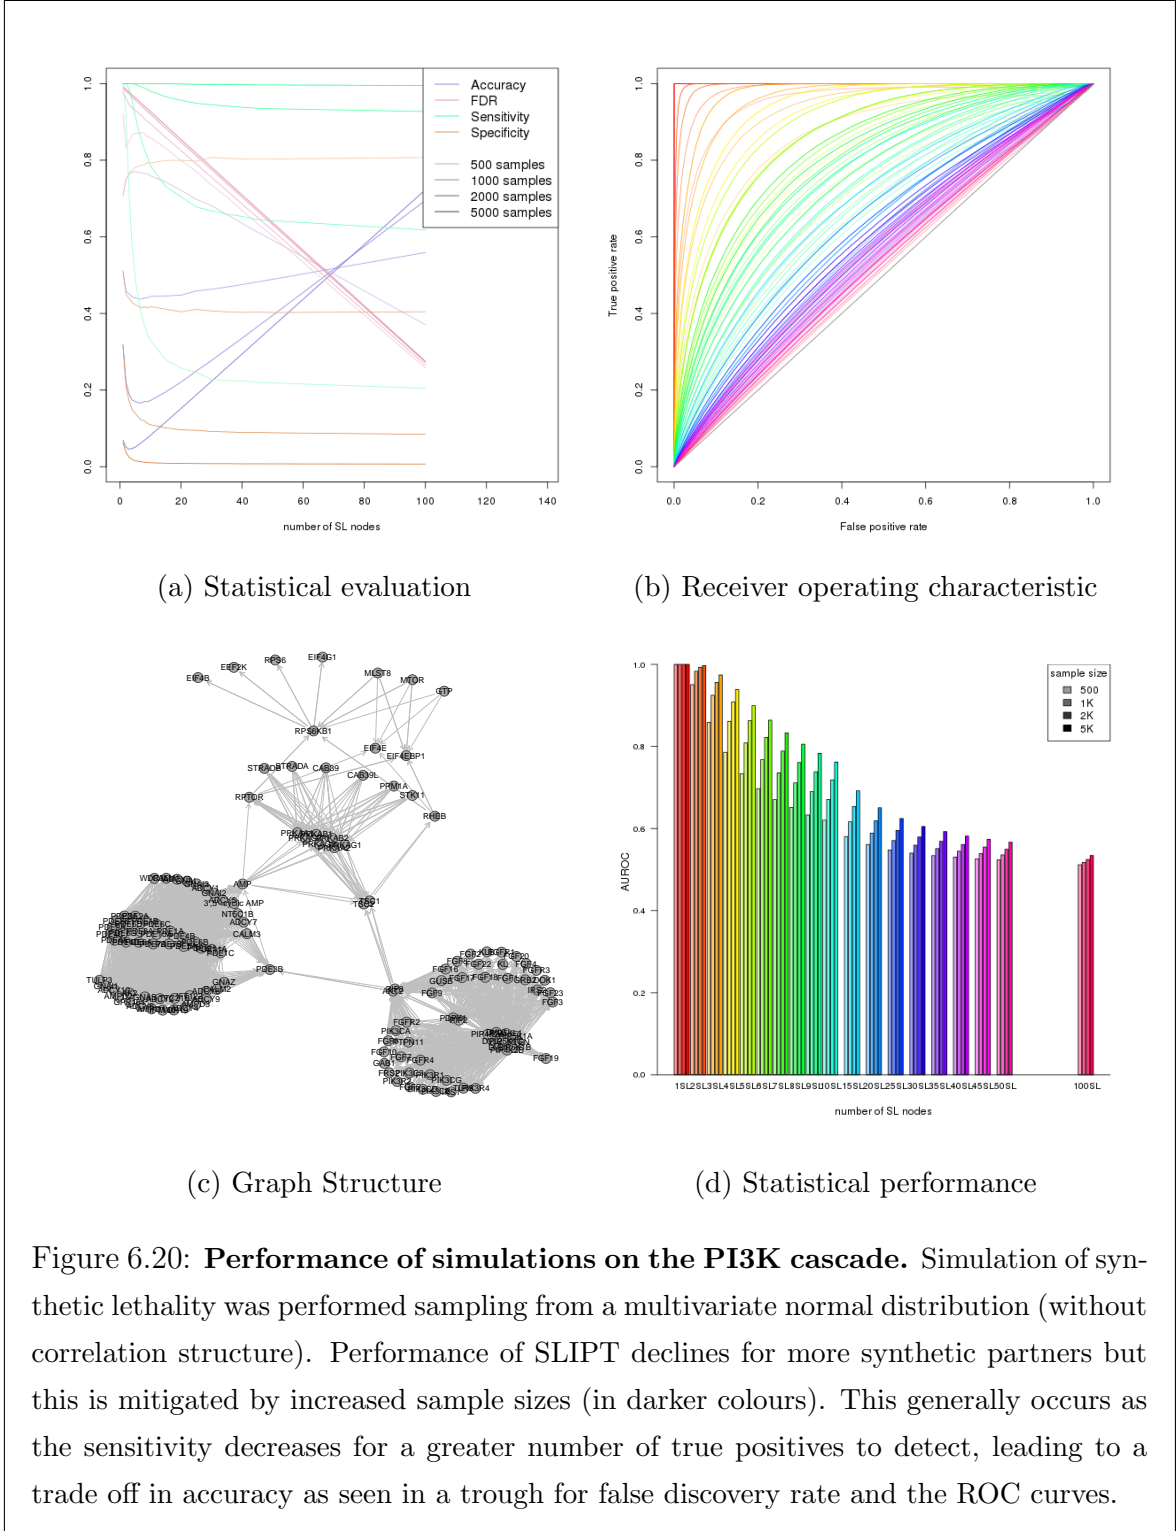

This interpretation is consistent with the poorly performing simulations in inhibiting graphs having a low sensitivity (in Figures O.29–O.39). These simulations still show high specificity and accuracy with a low false discovery rate for synthetic lethal detection with p-value (adjusted by FDR) thresholds for SLIPT. Such results support

SLIPT as a stringent methodology to detect synthetic lethal interactions in large gene expression data, excluding the majority of false positives with many of those remaining belonging to synthetic lethal pathways.

6.3 Simulations over pathway-based graphs

Text

(a) Statistical evaluation

(b) Receiver operating characteristic

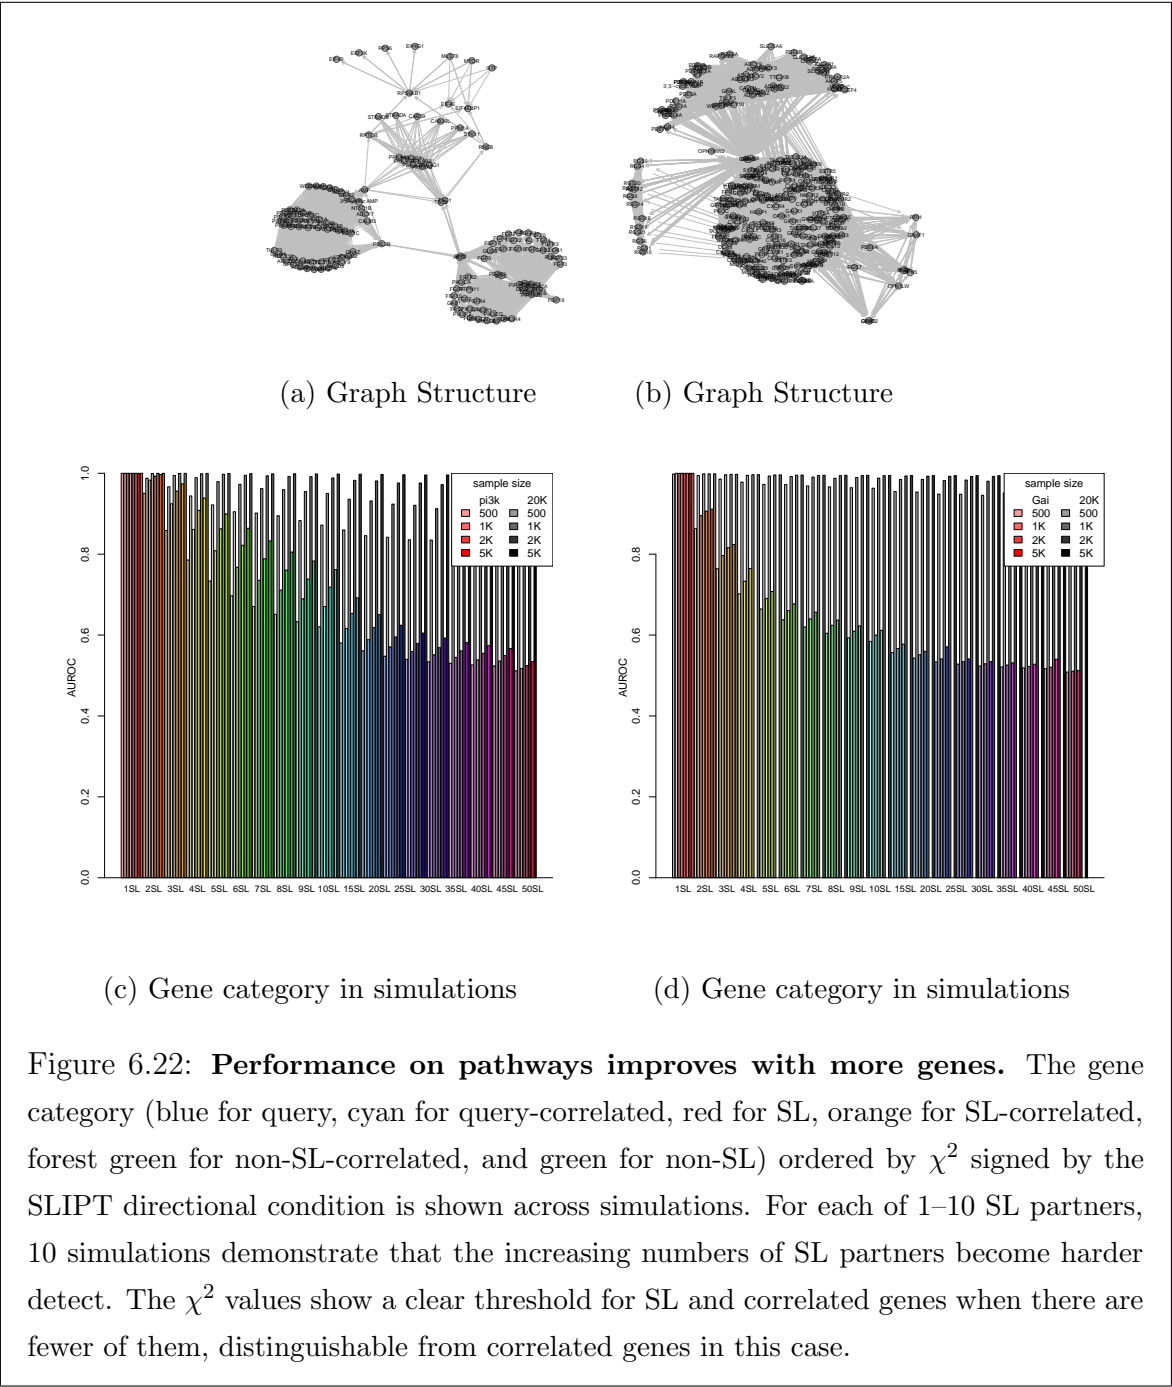

(c) Graph Structure

(d) Statistical performance

Figure 6.21: Performance of simulations including the PI3K cascade. Simulation of synthetic lethality was performed sampling from a multivariate normal distribution (without correlation structure). Performance of SLIPT declines for more synthetic partners but this is mitigated by increased sample sizes (in darker colours). This generally occurs as the sensitivity decreases for a greater number of true positives to detect, leading to a trade off in accuracy as seen in a trough for false discovery rate and the ROC curves.

6.3.1 Pathway Structures in a Simulated Human Genome

6.4 Discussion

Text

6.5 Summary

Text

Aims

- A Model of Synthetic Lethal Genes in Gene Expression Data
- Comparison of SLIPT to Alternative Approaches
- Simulations of Known Synthetic Lethal Genes within Pathway Networks

Summary

- We have designed a straight-forward rational query-based synthetic lethal detection method with the example of application to *CDH1* in cancer gene expression
- I have developed a simulation pipeline to generate continuous gene expression with pathway structure including a procedure to simulate synthetic lethality
- The simulation procedure shows that SLIPT is robust across pathway structures and has desirable performance compared to other statistical techniques
